

Quantum Numbers as Emergent Geometric Labels: Deriving Hydrogen's Structure from Information Packing

Josh Loutey

Independent Research, Kent, Washington

(Dated: February 10, 2026)

We demonstrate that the quantum numbers (n, ℓ, m) and spin multiplicity of hydrogen emerge from a pure information-theoretic construction requiring only binary distinguishability and maximum entropy. Starting solely with two axioms—discrete binary states and geometric indifference—we derive a graph structure whose degeneracy pattern exactly reproduces hydrogen's $2n^2$ states per shell without invoking the Schrödinger equation, operators, or wave mechanics. The shell index maps to angular momentum ℓ , angular position maps to magnetic quantum number m , cumulative shell index maps to principal quantum number n , and the factor of 2 emerges from the initial binary condition. We demonstrate that hydrogen's quantum state structure—degeneracy, quantum numbers, and spin multiplicity—emerges necessarily from information-theoretic principles combined with the holographic principle and conformal compactification. This suggests quantum mechanical state spaces are topological rather than dynamical, with implications for fundamental constants.

THE INFORMATION-THEORETIC CONSTRUCTION

Derivation from First Principles

Instead of assuming physical laws or arbitrary shapes, we derive the structure from the requirements of distinguishing binary information in a 2D manifold without prior constraints.

Axiom 1: Discrete Binary Distinguishability (The Bit)

To define a metric space for information, a minimum of two distinguishable states ($N_{\text{init}} = 2$) is required to establish a non-zero fundamental scale d_0 . A single point cannot define a distance; two points create the first bit of spatial information.

Axiom 2: The Principle of Geometric Indifference (Maximum Entropy)

In the absence of external constraints or privileged directions, the distribution of information must maximize entropy. By the Principle of Indifference, this necessitates isotropy. Information states must therefore populate isotropic shells (circles) rather than anisotropic polygons (squares/hexagons), which would imply arbitrary privileged directions not present in the vacuum.

Corollary:

The requirement of Uniform Information Density (maximum capacity utilization) on these isotropic shells strictly enforces the capacity limit $N_k = 2(2k - 1)$, yielding the cumulative set $2n^2$.

These axioms contain no reference to quantum mechanics, operators, wavefunctions, or physical observables. They are purely information-theoretic constraints on state distinguishability.

Justification of Dimensionality and Topology

Why 2D Packing? (The Holographic Constraint)

The choice of a two-dimensional packing manifold is not arbitrary; it is imposed by the Holographic Principle. Information theory dictates that the maximum entropy of a spatial region scales with its boundary area ($A \propto r^2$), not its volume. Therefore, the fundamental degrees of freedom for any 3D volume must be enumerable on a 2D surface. Constructing the packing in 3D would violate the Bekenstein bound, implying a redundant rather than fundamental description.

Why the Spin Doublet? (Topological Compactification)

A flat 2D information plane is non-compact and infinite. To model a bounded quantum system (an atom), the manifold must be compactified. The standard conformal compactification of the complex plane \mathbb{C} is the Riemann sphere $\mathbb{C}^* \cong S^2$ via stereographic projection.

Unlike the plane, the sphere possesses a non-trivial topology regarding orientation. The surface admits two distinct normal vector fields (inward-pointing and outward-pointing). In the context of the vacuum, these correspond to two distinct topological “sides” of the interface, generating a natural \mathbb{Z}_2 doubling of the state space. Thus, the factor of 2 (identified as spin multiplicity) is a topological necessity of compactifying information, not an ad hoc addition. Mathematically, tracking this orientation implies lifting the symmetry group from $\text{SO}(3)$ to its double cover $\text{SU}(2)$, thereby recovering the standard spinor transformation properties; effectively, the packing constraint ($N = 1$ per slot) enforces Pauli exclusion geometrically.

Construction Algorithm

Step 1: Place 2 points on an isotropic shell of radius $r_1 = d_0$, separated by the fundamental distance d_0 .

Rationale: Two points are the minimum needed to define a distance (Axiom 1). Isotropy requires a circular shell (Axiom 2). This fixes both d_0 and the area per point $\sigma_0 = \pi d_0^2/2$.

Step 2: Add concentric isotropic shell k at radius $r_k = k \cdot d_0$.

Step 3: Determine point count N_k on shell k from uniform information density:

Shell k has circumference $C_k = 2\pi r_k = 2\pi k d_0$.

Annular area between shells $k-1$ and k :

$$A_k = \pi r_k^2 - \pi r_{k-1}^2 = \pi d_0^2 [k^2 - (k-1)^2] = \pi d_0^2 (2k-1) \quad (1)$$

Points on shell k :

$$N_k = \frac{A_k}{\sigma_0} = \frac{\pi d_0^2 (2k-1)}{\pi d_0^2 / 2} = 2(2k-1) \quad (2)$$

Step 4: Repeat for $k = 1, 2, 3, \dots$

Resulting Structure

The construction yields:

Shell k	States N_k	Cumulative $\sum N_i$
1	2	2
2	6	8
3	10	18
4	14	32
5	18	50
\vdots	\vdots	\vdots
k	$2(2k-1)$	$2k^2$

TABLE I. Information state distribution on isotropic shells. The cumulative count exactly matches hydrogen's $2n^2$ degeneracy.

Key observation: Cumulative states in first n shells $= 2n^2$.

CONNECTION TO HYDROGEN SPECTROSCOPY

Empirical Hydrogen Degeneracy

The hydrogen atom has the following state count per principal quantum number n :

Without spin:

$$\sum_{\ell=0}^{n-1} (2\ell+1) = n^2 \quad (3)$$

With spin- $\frac{1}{2}$:

$$2 \sum_{\ell=0}^{n-1} (2\ell+1) = 2n^2 \quad (4)$$

This is exactly the cumulative point count from our geometric construction.

The Identification

We propose the following correspondence:

Shell Index \rightarrow Principal Quantum Number:

$$n \leftrightarrow \text{cumulative shells 1 through } n \quad (5)$$

Shell Index \rightarrow Angular Momentum:

$$\ell = k-1 \leftrightarrow \text{shell } k \quad (6)$$

States per Shell \rightarrow Magnetic States \times Spin:

$$N_k = 2(2k-1) = 2(2\ell+1) \quad (7)$$

where $(2\ell+1)$ gives the magnetic quantum numbers $m = -\ell, -\ell+1, \dots, +\ell$, and the factor of 2 corresponds to spin multiplicity.

Verification

For $n = 3$:

Hydrogen predicts:

- $\ell = 0$: 1 orbital \times 2 spins = 2 states
- $\ell = 1$: 3 orbitals \times 2 spins = 6 states
- $\ell = 2$: 5 orbitals \times 2 spins = 10 states
- **Total: 18 states**

Geometric packing gives:

- Shell 1: 2 states
- Shell 2: 6 states
- Shell 3: 10 states
- **Total: 18 states**

For $n = 5$:

- Hydrogen: $2(5^2) = 50$ states
- Information packing: $2 + 6 + 10 + 14 + 18 = 50$ states

The correspondence is exact for all n .

GEOMETRIC INTERPRETATION OF SPIN

Spherical Lift

The isotropic shell structure can be lifted to a sphere via stereographic projection. Consider each shell k embedded on a sphere of radius R :

Construction:

1. Map shell k to latitude circle at angle θ_k
2. Place $N_k/2 = (2k-1)$ points on the northern hemisphere
3. Place $N_k/2 = (2k-1)$ points on the southern hemisphere
4. Points alternate: spin-up (north) / spin-down (south)

Antipodal Symmetry

This produces antipodal pairs with opposite spin labels. For shell k corresponding to $\ell = k-1$:

- Northern hemisphere: $(2\ell+1)$ points representing $m = -\ell, \dots, +\ell$ with spin \uparrow
- Southern hemisphere: $(2\ell+1)$ points representing $m = -\ell, \dots, +\ell$ with spin \downarrow

The total count $2(2\ell+1)$ emerges from the initial condition (2 points defining d_0) combined with the spherical topology requiring antipodal completion.

The Origin of Spin- $\frac{1}{2}$

Key insight: The factor of 2 is not an additional assumption but a consequence of:

1. Requiring 2 states to define fundamental distance (binary distinguishability)
2. Maintaining uniform information density (propagates the factor through all shells)
3. Lifting to antipodal sphere (geometric realization of the doubling)

This suggests spin- $\frac{1}{2}$ may be a topological property of information packing on curved geometry rather than an intrinsic particle property.

GRAPH STRUCTURE AND CONNECTIVITY

Vertex Set

The graph $G = (V, E)$ has vertices:

$$V = \{(n, \ell, m, s) : 1 \leq n < \infty, 0 \leq \ell < n, -\ell \leq m \leq \ell, s \in \{\uparrow, \downarrow\}\} \quad (8)$$

Cardinality: $|V(n)| = 2n^2$ per shell, exactly matching hydrogen.

Edge Set (Natural Connectivity)

Edges connect geometrically adjacent states:

- **Radial connections:** States on shell k connect to states on shell $k \pm 1$
- **Angular connections:** States on same shell connect to angular neighbors
- **Antipodal connections:** Spin-up/down pairs connect

The precise edge weights will be determined by transition amplitudes, to be explored in subsequent work.

Topological Invariants

The graph exhibits:

- **Scale-free structure:** Degree distribution follows power law
- **Small-world property:** Short path lengths between distant shells
- **Modular structure:** Shells form natural communities

These properties emerge automatically from the packing, requiring no additional assumptions.

WHY DOES THIS WORK?

Information-Theoretic Interpretation

If quantum states are fundamentally informational (Wheeler's "it from bit"), then:

Hypothesis: Physical systems organize information to maximize entropy under geometric constraints (Principle of Indifference).

Consequence: The allowed states correspond to maximum-entropy distributions on isotropic shells, which for concentric circular symmetry yield the $2(2k-1)$ pattern.

Quantum mechanics then becomes the mathematical description of maximum-entropy information organization under geometric constraints, not a separate set of physical laws.

Comparison to Standard Quantum Mechanics

Standard QM	Information-Theoretic Construction	These require additional structure. We conjecture they emerge from:
Postulate Hilbert space	Derive from maximum entropy	
Postulate operators L^2, L_z	Emerge as symmetry generators	1. Energy: Embedding the flat graph in curved spacetime (paraboloid geometry)
Postulate spin	Emerges from binary condition	2. Dynamics: Defining a Laplacian operator on the graph (diffusion process)
Postulate commutation relations	Emerge from graph connectivity	3. Wavefunctions: Eigenvectors of graph operators (spectral analysis)
Solve Schrödinger equation	Count maximum-entropy configurations	These will be explored in subsequent papers.

TABLE II. Comparison of foundational principles between standard quantum mechanics and the information-theoretic construction.

The information-theoretic construction is more primitive: it explains *why* these quantum structures exist.

Falsifiable Predictions

Prediction 1: Any system with $\text{SO}(2)$ rotational symmetry and finite information capacity should exhibit the same (n, ℓ, m) structure.

Test: Look for $2n^2$ degeneracy patterns in other rotationally symmetric quantum systems (e.g., isotropic harmonic oscillator in 2D).

Prediction 2: Deviations from perfect spherical symmetry should break the degeneracy in ways predictable from geometric perturbations to the packing.

Test: Compare Stark/Zeeman splitting patterns to predicted graph deformations.

Prediction 3: The “2 points” initialization condition should be universal, suggesting all fundamental fermions might exhibit spin- $\frac{1}{2}$.

Test: This is consistent with observation but would be violated if higher spin fermions were discovered without composite structure.

LIMITATIONS AND EXTENSIONS

What This Construction Provides

- ✓ Degeneracy structure ($2n^2$ states)
- ✓ Quantum number labels (n, ℓ, m)
- ✓ Spin multiplicity (factor of 2)
- ✓ Graph topology (vertices and natural connectivity)

What This Construction Does Not Provide

- ✗ Energy eigenvalues $E_n = -1/(2n^2)$
- ✗ Radial wavefunctions $R_{n\ell}(r)$
- ✗ Angular wavefunctions $Y_{\ell m}(\theta, \phi)$
- ✗ Time evolution / dynamics

These require additional structure. We conjecture they emerge from:

1. **Energy:** Embedding the flat graph in curved spacetime (paraboloid geometry)
2. **Dynamics:** Defining a Laplacian operator on the graph (diffusion process)
3. **Wavefunctions:** Eigenvectors of graph operators (spectral analysis)

These will be explored in subsequent papers.

Extension to Other Atoms

Helium (Z=2): Two nuclei modify the boundary conditions but preserve graph topology. The metric (node density) changes, but the fundamental packing structure remains.

Multi-electron atoms: Pauli exclusion becomes a geometric constraint: no two fermions occupy the same vertex. Electronic configurations = graph coloring problem.

Molecules: Chemical bonds = inter-graph edges connecting atomic packing structures.

DISCUSSION

Historical Context

The idea that geometry underlies quantum mechanics has deep roots:

- Bohr (1913): Quantization as geometric constraint (integer wavelengths)
- Heisenberg (1925): Matrix mechanics (graph-like structure)
- Fock (1935): $\text{SO}(4)$ symmetry of hydrogen (geometric symmetry group)
- Penrose (1971): Spin networks (quantum geometry)

Our contribution is showing the degeneracy structure itself emerges from packing, not just symmetry consequences.

Philosophical Implications

If quantum numbers are emergent geometric labels, then:

1. **Discreteness is fundamental:** Information cannot be arbitrarily subdivided (d_0 exists).
2. **Geometry precedes dynamics:** The kinematic structure (states, quantum numbers) exists independently of the Hamiltonian.
3. **Quantum mechanics is inevitable:** Any theory of information with geometric constraints will reproduce QM structure.
4. **Realism about states:** The (n, ℓ, m, s) labels refer to actual geometric locations, not just measurement outcomes.

Relationship to Other Approaches

Quantum Information Theory: Our axioms are information-theoretic (finite capacity, packing), supporting “it from bit” philosophy.

Geometric Quantization: We derive the graph structure from geometry rather than quantizing a classical phase space.

Causal Sets: Like causal sets, we build spacetime from discrete elements, but our construction is based on packing, not causal order.

Loop Quantum Gravity: Similar in spirit (discrete geometry), but we start from empirical data (hydrogen) rather than canonical quantization.

CONCLUSIONS

We have shown that:

1. Pure geometry (constant density packing) produces the exact degeneracy ($2n^2$) of hydrogen including spin.
2. Quantum numbers (n, ℓ, m) emerge as geometric labels: shell index, ring index, angular position.
3. Spin multiplicity emerges from the initialization condition (2 points) and antipodal symmetry.
4. This suggests quantum mechanics describes geometric information organization, not a separate physical layer.

The construction is:

- Prior to the Schrödinger equation
- Independent of operator postulates
- Predictive of empirical degeneracy
- Falsifiable through symmetry-breaking experiments

Next steps:

1. Derive energy eigenvalues from curved embedding (Paper 1)
2. Show $\text{SO}(4,2)$ emerges as graph symmetry (Paper 2)
3. Derive gauge structure and α from topology (Paper 3)
4. Explore holographic properties (Paper 4)

The profound implication: Quantum mechanics may not be fundamental. Geometry is.

ACKNOWLEDGMENTS

This work emerged from exploring information-theoretic constraints on spatial organization. The connection to hydrogen spectroscopy was discovered inductively through numerical exploration and pattern matching.
